Abstract—This document aims to detail the implementation of a binary genetic algorithm, a hill climbing algorithm and how the former could be hybridised using the latter.

Index Terms—genetic algorithm, hill climber algorithm, nature inspired methods, hybridisation

I. Introduction

This document aims to detail how a binary genetic algorithm and how a hill climbing algorithm is implemented. The former represents a "weak" method that can be used to solve a pleothera of problems. The latter represents an effective algorithm of the local-search class. In addition to the previously stated, the document details a way to hybridise the genetic algorithm with the hill climbing algorithm, thus gaining a better performance.

II. GENETIC ALGORITHMS

A. Definition

A genetic algorithm represents a way to solve problems from the combinatorial, numerical, optimisation, timetabling and scheduling, robotics etc. spaces, in general being very weakly coupled to problems, thus can be used in multiple problem spaces with rather little modifications.

B. Notations

Individual:

$$Individual = (genes, value_{fitness}) \tag{1}$$

$$genes = \{x | x \in \{0, 1\}\}\$$
 (2)

$$value_{fitness} \in \mathbb{Q}$$
 (3)

$$Individual_{decode} = (decode(genes), value_{fitness})$$
 (4)

Population:

$$Population = \{individual_1, individual_2, \dots\}$$
 (5)

$$Population_{decoded} = \{ \\ individual_{1_{decoded}}, \\ individual_{2_{decoded}}, \\ \dots$$

Population:

$$Population = \{individual_1, individual_2, \dots\}$$
 (7)

Number of individuals in a population:

$$|Population| = n, n \in \mathbb{N}, n > 1$$
 (8)

Number of generations:

$$generation \in \mathbb{N}$$
 (9)

Encode individual to binary function:

$$encode: x \to \{v | v \in \{0, 1\}\}\$$
 (10)

Decode individual from binary function:

$$decode: \{v|v \in \{0,1\}\} \to x \tag{11}$$

Criteria function:

criteria:(

 $Population_{decoded},$

Population fitness,

generation

$$) \rightarrow \{True, False\}$$
 (12)

Fitness function:

$$fitness: individual_{decoded} \to \mathbb{Q}$$
 (13)

Selection function:

 $individual_{decoded}$,

 $individual_{decoded}$

$$) \rightarrow ($$

 $individual_{decoded}$,

 $individual_{decoded}$

) (14)

Mutation function:

$$mutate: individual \rightarrow individual$$
 (15)

Crossover point:

$$bit_{crossover} \in \mathbb{N}$$
 (16)

Mutation chance:

} (6)

$$mutation \in \mathbb{Q}, mutation \in [0, 1]$$
 (17)

C. High-level implementation

As a high-level view, the algorithm performs the following steps:

- 1) Generate a population of n binary-encoded individuals randomly.
- 2) While the criteria function *criteria* does not return True, be the criteria number of generations, "fitness" values of the population or something else:
 - a) Calculate the "fitness" of each individual in the population using the function *fitness*.
 - b) Sort the population by the "fitness" value.
 - c) Create a new and empty population set *Population'*.
 - d) For n/2 iterations:
 - i) Perform the selection of parents for the next individuals using the *selection* function.
 - ii) Crossover the 2 selected parents at the crossover bit, generating 2 children, child₁, child₂.
 - iii) Mutate $child_1$, given the mutate function and the mutation chance using an internal mutation function.
 - iv) Mutate $child_2$, given the mutate function and the mutation chance.
 - v) Add child1 and child2 to Population'
 - e) Perform Population = Population'
- 3) Return the most "fit" individual in the population, represented by the individual on which the *fitness* function returned the highest score.

D. Time complexity

The time complexity of genetic algorithms can be difficult to determine as it depends on many factors such as the size of the population, the number of generations and the specifics of the algorithm. In general, this would be considered $\mathcal{O}(n^2)$ or $\mathcal{O}(n^3)$.

E. Fitness function

The fitness function represents the function we want to optimise for. Due to the selection process of the genetic algorithm returning the 2 most "fit" individuals, and using them as seeds for the children of the next generation, this can be infered.

F. Selection function

The selection function aims to select 2 of the most "fit" individuals from the population. This function is provided by the user of the genetic algorithm in order to improve the flexibility of the algorithm.

G. Crossover function

The algorithm includes a crossover function. The crossover takes the 2 given individuals $parent_1$, $parent_2$ and performs the following:

- 1) For child $child_1$, the $bit_i < bit_{crossover}$ bits from the parent $parent_1$'s genes and $bit_i \ge bit_{crossover}$ bits from the $parent_2$'s genes are borrowed.
- 2) For child $child_2$, the $bit_i < bit_{crossover}$ bits from the parent $parent_2$'s genes and $bit_i \ge bit_{crossover}$ bits from the $parent_1$'s genes are borrowed.

For a parent $parent_1.genes = 01010101$, a parent $parent_2.genes = 10101010$, and a crossover bit $bit_{crossover} = 3$, the results would be:

- 1) $child_1.genes = 01101010$
- 2) $child_2.genes = 10010101$

H. Mutation function

The mutation function aims to increase the possibility of a greater solution and the chance of escaping the local optima of the final solution. In this function, a random bit bit_i of the individual's genes is flipped and the individual is returned.

Having this performed, the new individual might have a lower or higher "fitness" than the rest of the population, "fitness" which will be captured by the *fitness* and later "judged" by the *select* functions.

In case the individual performs lower due to the change, the individual is dropped. The other way around is also possible: in case the individual performs higher (possibly even significantly so), the individual is promoted by the *select* function.

I. Generations

The algorithm does not aim to provide the best solution firsttry, thus it needs time for it to improve. Given enough time (expressed in generations), it can provide better solutions, as the "fitness" of the individual increases.

III. HILL CLIMBING ALGORITHM

A. Definition

Hill climbing is a mathematical optimisation technique belonging to the family of local search. The algorithm is iterative and starts with an arbitrary solution to a given problem, which attempts to perfect by performing incremental changes.

The algorithm may regrettably become ensnared within local optima, precluding its ability to escape from such configurations. Nevertheless, it continues to find utility across diverse problem domains, owing to its computational efficiency and swift derivation of an acceptably effective solution.

B. Notations

Step:

$$Step \in \mathbb{Q}, Step \neq 0$$
 (18)

Acceleration:

$$Acceleration \in \mathbb{Q}, Acceleration \neq 0$$
 (19)

Precision:

$$Precision \in \mathbb{Q}, Precision \neq 0$$
 (20)

Iterations:

$$Iterations \in \mathbb{N}, Iterations \in [-1, +\inf)$$
 (21)

Function to optimise:

$$f: \mathbb{R} \to \mathbb{R},$$
 (22)

C. High-level implementation

As a high-level view, the algorithm performs the following steps:

- 1) Picks an x_{best} at random.
- 2) Set iteration = 0.
- 3) Set $score_{before} = NULL$.
- 4) Set $step_{best} = step$.
- 5) Set $score_{best} = f(x_{best})$.
- 6) While $iteration < iterations \lor score_{before} : NULL \lor |score_{best} score_{before}| > precision:$
 - a) For each step $step_i \in \{$ $step_{best} * acceleration,$ $step_{best} * -acceleration,$ $step_{best} * 1/acceleration,$ $step_{best} * -1/acceleration$ $\}$:
 - i) If $f(x_{best} + step_i) > score_{best}$, perform $step_{best} = step_i$, $score_{best} = f(x_{best} + step_i)$, $x_{best} = x_{best} + step_i$.
 - b) Peform iteration = iteration + 1.
- 7) Return x_{best} .

D. Time complexity

The algorithm has a low time complexity of $\mathcal{O}(n)$, thus it is usually implemented on systems that would need an approximate solution, them often being realtime systems.

E. Continuous space hill climbing

Since the optima of a problem might not be found using a value x that are modified using discreet value, we will have to resume to modifying the value x in a continuous manner.

In order to perform the above, we will continuously use a parameter named acceleration, parameter which will improve x in smaller increments for each iteration. This way, the algorithm can find the optima of a given problem with a higher precision than a discreet space hill climber.

In order to perform this, we will call the f function on each $x * step_i$, where:

$$\begin{split} step_i &\in \{ \\ step_{best} * acceleration, \\ step_{best} * - acceleration, \\ step_{best} * 1/acceleration, \\ step_{best} * - 1/acceleration \end{split}$$

IV. HYBRIDISATION

A. Motivation

While the 2 algorithms can be used independently of each other and can in turn produce good results, they can also be merged into 1 single algorithm that performs both functions at the same time in the hopes that the solutions are found faster.

B. High-level implementation

As a high-level view, the algorithm performs the following steps:

- 1) While $generations < generations_{limit}$:
 - a) Run the binary genetic algorithm, returning $Population_{decoded}$
 - b) For each $individual_{decoded} \in Population_{decoded}$:
 - i) Run the hill climbing algorithm on the individual individual_{decoded}, returning individual'_{decoded}
 - ii) Run $individual_{decoded} = individual'_{decoded}$

C. Time complexity

While the algorithm appears to have a low complexity at first, this would have the complexity $\mathcal{O}(n^2 + n)$, as both the genetic and the hill climbing algorithms are run in tandem.

D. Testing

During testing with a function $f:[0,31] \to \mathbb{R}, f(x) = x^3 - 60 * x^2 + 900 * x + 100$ with an maxima of 10 in the given domain, the algorithm:

- 1) Did not escape the given boundaries (issue encountered with the genetic algorithm).
- 2) Did provide a better approximation of the solution (issue encountered with the hillclimber algorithm).

Thus, the hybridisation provided a better solution for the given problem.
